# A note on general no-cloning theorem for black boxes 

Alexey E. Rastegin*<br>Department of Theoretical Physics, Irkutsk State University, Gagarin Bv. 20, Irkutsk 664003, Russia

#### Abstract

In view of recent general no-cloning theorem for black boxes, a conceivable equivalence between the unambiguous discrimination and exact probabilistic cloning is discussed. No-cloning principle for orthogonal states in composite systems is revisited.

PACS numbers: 03.67.Ac, 03.65.Ta, 03.67.Dd

In Ref. 1], the authors proposed "general no-cloning theorem for black boxes". This is a novel valuable result which posed a cloning-discrimination equivalence [2]. Let we have two black boxes $\mathcal{O}_{1}$ and $\mathcal{O}_{2}$ of any kind. Consider a discriminating tester between them which gives one of two answers, ' $\mathcal{O}_{1}$ ' and ' $\mathcal{O}_{2}$ '. In general, this discrimination is not error-free. For quantum states, such a scheme was developed by Helstrom [3]. Denoting the worst-case error probability by $p_{w c}$, the following statement takes place 1]: "two black boxes cannot be perfectly cloned by a single use unless $p_{w c}=0$ and $p_{w c}=1 / 2$." For quantum states, this result can be reformulated as cloning-discrimination equivalence [2]. So, quantum states from a prescribed set can be perfectly cloned if and only if they can be perfectly discriminated in a single observation-test. However, this statement means only deterministic process for cloning. But quantum states can sometimes be cloned exactly via probabilistic procedure invented by Duan and Guo (4].

There are some natural questions related to the above general no-cloning theorem. One of them concern an interdependence between unambiguous discrimination and exact cloning. Namely, is it possible to obtain any equivalence theorem? Or, conversely, there exist counterexamples? Let $U D S$ denote an unambiguous discrimination scheme with probability of conclusive answer $p_{\text {con }}>0$, and let $E C M$ denote an exact cloning machine with probability of success $p_{\text {suc }}>0$, both with respect to prescribed set $S=\left\{\rho, \rho^{\prime}\right\}$. In general, we have the implication:

$$
\begin{equation*}
" U D S \text { exists } " \Longrightarrow " E C M \text { exists" } \tag{1}
\end{equation*}
$$

where $p_{\text {suc }} \geq p_{\text {con }}$ obviously. By means of $U D S$, we can always discriminate an unknown input $\rho^{(i)}$ unambiguously. Since the state $\rho^{(i)}$ is identified, we merely reprepare a desired number of exact clones. Moreover, the existing unambiguous discrimination implies a possibility of state separation [5]. Quantum state separation introduced by Chefles and Barnett involves both the unambiguous discrimination and exact cloning as particular cases [6]. Further, if two black boxes cannot be discriminated unambiguously then an existence of $E C M$ is left open. On the other hand, a given device for exact cloning itself does not allow to build unambiguous discrimination scheme. Indeed, the exact cloning is probabilistic in character, and the arguments of Ref. 1] cannot be extended to this case.

Thus, nothing can be said for possibility of unambiguous discrimination in general. For pair $\left\{\rho, \rho^{\prime}\right\}$ of quantum states, the necessary and sufficient condition for $U D S$ is written as $\operatorname{supp}(\rho) \neq \operatorname{supp}\left(\rho^{\prime}\right)$, where $\operatorname{supp}(\rho)$ denotes the support space of density operator $\rho$. In other words, two density operators with identical supports cannot be discriminated unambiguously. Moreover, the following result has been proved [5]. Any state separation is possible if and only if $\operatorname{supp}(\rho) \neq \operatorname{supp}\left(\rho^{\prime}\right)$. But this is condition for that we should attain each form of separation including the unambiguous discrimination. So we may ask whether two states with the same support can be cloned exactly. This is not forbidden by $U D S$-impossibility itself. The question is formally posed as:

$$
\begin{equation*}
" U D S \text { does not exist" } \Longrightarrow \quad E C M \text { does not exist"? } \tag{2}
\end{equation*}
$$

In principle, this question seems to be difficult enough. But there is the case of commuting density operators in which an analysis is essentially simplified.

The most general form of possible state change in quantum mechanics is described within the formalism of quantum operations [7]. Let $\mathcal{H}_{\text {in }}$ and $\mathcal{H}_{\text {out }}$ be finite-dimensional Hilbert spaces. Consider any process $\mathcal{E}$ that leads to a map

$$
\begin{equation*}
\rho_{\text {in }} \mapsto \rho_{\text {out }}:=\operatorname{tr}\left\{\mathcal{E}\left(\rho_{\text {in }}\right)\right\}^{-1} \mathcal{E}\left(\rho_{\text {in }}\right) \tag{3}
\end{equation*}
$$

where an input $\rho_{\text {in }}$ is some normalized state on $\mathcal{H}_{\text {in }}$ and an output $\rho_{\text {out }}$ is some normalized state on $\mathcal{H}_{\text {out }}$. When this map is consistent with the quantum laws, $\mathcal{E}$ is a quantum operation with the input space $\mathcal{H}_{\text {in }}$ and the output space $\mathcal{H}_{\text {out }}$ [7]. The denominator in Eq. (3) is the probability that the above process occurs. So one demands that $0 \leq \operatorname{tr}\left\{\mathcal{E}\left(\rho_{\mathrm{in}}\right)\right\} \leq 1$ for each input $\rho_{\mathrm{in}}$. In addition, a map $\mathcal{E}$ must be linear and completely positive [7]. Due to the operator-sum representation [7], the map $\mathcal{E}$ is a quantum operation if and only if

$$
\begin{equation*}
\mathcal{E}\left(\rho_{\mathrm{in}}\right)=\sum_{m} \mathrm{E}_{m} \rho_{\mathrm{in}} \mathrm{E}_{m}^{\dagger} \tag{4}
\end{equation*}
$$

for some operators $\mathrm{E}_{m}$ mapping the input space $\mathcal{H}_{\text {in }}$ to the output space $\mathcal{H}_{\text {out }}$. The condition $0 \leq \operatorname{tr}\left\{\mathcal{E}\left(\rho_{\text {in }}\right)\right\} \leq 1$ implies that

$$
\begin{equation*}
\sum_{m} \mathrm{E}_{m}^{\dagger} \mathrm{E}_{m} \leq \mathbf{1}_{\mathrm{in}} \tag{5}
\end{equation*}
$$

where $\mathbf{1}_{\text {in }}$ denotes the identity on the input space. Let $\{|i\rangle\}$ be an orthonormal basis in $\mathcal{H}_{\text {in }}$, and let $\{|\mu\rangle\}$ be an orthonormal basis in $\mathcal{H}_{\text {out }}$. With respect to these bases, each operator $\mathrm{E}_{m}$ is represented by some matrix of size $\operatorname{dim}\left(\mathcal{H}_{\text {out }}\right) \times \operatorname{dim}\left(\mathcal{H}_{\text {in }}\right)$. In particular, the operator $|\mu\rangle\langle i|$ is assigned by the matrix whose $(\mu, i)$-entry is one and the remaining entries are zero. Therefore, we can write

$$
\begin{equation*}
\mathrm{E}_{m}=\sum_{\mu i} g_{\mu i}^{(m)}|\mu\rangle\langle i| \tag{6}
\end{equation*}
$$

where complex numbers $g_{\mu i}^{(m)} \equiv\langle\mu| \mathrm{E}_{m}|i\rangle$. Suppose that positive operator A with eigenvalues $a_{i}$ is diagonal with respect to the basis $\{|i\rangle\}$. Then we obtain

$$
\begin{equation*}
\mathcal{E}(\mathrm{A})=\sum_{m} \sum_{\mu i} \sum_{\nu j} g_{\mu i}^{(m)} \bar{g}_{\nu j}^{(m)}|\mu\rangle\langle i| \mathrm{A}|j\rangle\langle\nu|=\sum_{\mu \nu} c_{\mu \nu}|\mu\rangle\langle\nu| \tag{7}
\end{equation*}
$$

where coefficients $c_{\mu \nu}=\sum_{m i} g_{\mu i}^{(m)} \bar{g}_{\nu i}^{(m)} a_{i}$. So, the diagonal elements of output $\mathcal{E}(\mathrm{A})$ are expressed as

$$
\begin{equation*}
c_{\mu \mu}=\sum_{i} a_{i} \sum_{m}\left|g_{\mu i}^{(m)}\right|^{2}=\sum_{i} x_{\mu i} a_{i} \tag{8}
\end{equation*}
$$

where positive numbers $x_{\mu i} \equiv \sum_{m}\left|g_{\mu i}^{(m)}\right|^{2}$. In other words, the diagonal elements of $\mathcal{E}(\mathrm{A})$ are linear combinations of the diagonal elements of input $A$.

In the context of cloning, we denote $\mathcal{H}_{\mathrm{in}}=\mathcal{H}$ and $\mathcal{H}_{\text {out }}=\mathcal{H} \otimes \mathcal{H}$. The basis vectors $|\mu\rangle$ are merely expressed as $|\mu\rangle=|i\rangle \otimes|j\rangle$. The exact cloning demands that

$$
\begin{equation*}
\rho \mapsto \rho \otimes \rho, \quad \rho^{\prime} \mapsto \rho^{\prime} \otimes \rho^{\prime} \tag{9}
\end{equation*}
$$

Putting positive operators $\mathrm{A}=\operatorname{tr}\{\mathcal{E}(\rho)\} \rho$ and $\mathrm{A}^{\prime}=\operatorname{tr}\left\{\mathcal{E}\left(\rho^{\prime}\right)\right\} \rho^{\prime}$, the relations (19) are reduced to

$$
\begin{equation*}
\mathcal{E}(A)=A \otimes A, \quad \mathcal{E}\left(A^{\prime}\right)=A^{\prime} \otimes A^{\prime} \tag{10}
\end{equation*}
$$

If the two operators $\rho, \rho^{\prime}$ (and therefore $\mathrm{A}, \mathrm{A}^{\prime}$ ) have the same support then we can take $\mathcal{H}=\operatorname{supp}(\rho)=\operatorname{supp}\left(\rho^{\prime}\right)$ without loss of generality. So both the operators $A$ and $A^{\prime}$ are strictly positive. Then we wonder whether the relations (10) are possible for those strictly positive matrices that give distinct density matrices after normalization. In other words, we demand that $A$ and $A^{\prime}$ be not related linearly, $A^{\prime} \neq c A$. We consider the case in which both the operators $A$ and $A^{\prime}$ are diagonal with respect to the basis $\{|i\rangle\}$. Then both the outputs $A \otimes A$ and $A^{\prime} \otimes A^{\prime}$ are represented by diagonal matrices. In particular, for $2 \times 2$-inputs

$$
\mathrm{A}=\left[\begin{array}{cc}
\alpha & 0  \tag{11}\\
0 & \beta
\end{array}\right], \quad \mathrm{A}^{\prime}=\left[\begin{array}{cc}
\alpha^{\prime} & 0 \\
0 & \beta^{\prime}
\end{array}\right]
$$

with strictly positive diagonal elements, i.e. $\alpha, \beta, \alpha^{\prime}, \beta^{\prime}>0$, we have

$$
\mathbf{A} \otimes \mathbf{A}=\left[\begin{array}{cccc}
\alpha^{2} & 0 & 0 & 0  \tag{12}\\
0 & \alpha \beta & 0 & 0 \\
0 & 0 & \beta \alpha & 0 \\
0 & 0 & 0 & \beta^{2}
\end{array}\right], \quad \mathbf{A} \otimes \mathbf{A}=\left[\begin{array}{cccc}
\alpha^{\prime 2} & 0 & 0 & 0 \\
0 & \alpha^{\prime} \beta^{\prime} & 0 & 0 \\
0 & 0 & \beta^{\prime} \alpha^{\prime} & 0 \\
0 & 0 & 0 & \beta^{\prime 2}
\end{array}\right]
$$

From expression (8) for diagonal elements, we obtain the following three systems of equations:

$$
\text { (i) }:\left\{\begin{array}{c}
\alpha x+\beta y=\alpha^{2}  \tag{13}\\
\alpha^{\prime} x+\beta^{\prime} y=\alpha^{\prime 2}
\end{array}\right\}, \quad \text { (ii) }:\left\{\begin{array}{c}
\alpha \xi+\beta \eta=\alpha \beta \\
\alpha^{\prime} \xi+\beta^{\prime} \eta=\alpha^{\prime} \beta^{\prime}
\end{array}\right\}, \quad \text { (iii) }:\left\{\begin{array}{c}
\alpha u+\beta v=\beta^{2} \\
\alpha^{\prime} u+\beta^{\prime} v=\beta^{\prime 2}
\end{array}\right\}
$$

We ask whether all these systems have nonnegative solution simultaneously. Of course, we avoid the case $\alpha \beta^{\prime}=\alpha^{\prime} \beta$ in which $\alpha^{\prime} / \alpha=\beta^{\prime} / \beta=c$ and $A^{\prime}=c \mathrm{~A}$. With no loss of generality, we take $\alpha \beta^{\prime}>\alpha^{\prime} \beta$. Then the determinant $\Delta=\alpha \beta^{\prime}-\alpha^{\prime} \beta>0$ and each of the systems (i), (ii), (iii) has a unique solution. It turns out, however, that the systems
(i) and (iii) cannot have nonnegative solution simultaneously. Let us denote $k=\alpha^{\prime} / \alpha>0$ and $l=\beta^{\prime} / \beta>0$, then $\Delta>0$ is equivalent to $l>k$. Due to Cramer's rule, we have $y=\Delta_{y} / \Delta$ and $u=\Delta_{u} / \Delta$, where

$$
\Delta_{y}=\left|\begin{array}{cc}
\alpha & \alpha^{2}  \tag{14}\\
\alpha^{\prime} & \alpha^{\prime 2}
\end{array}\right|=\alpha \alpha^{\prime}\left(\alpha^{\prime}-\alpha\right)=\alpha^{3} k(k-1), \quad \Delta_{u}=\left|\begin{array}{cc}
\beta^{2} & \beta \\
\beta^{\prime 2} & \beta^{\prime}
\end{array}\right|=\beta \beta^{\prime}\left(\beta-\beta^{\prime}\right)=\beta^{3} l(1-l)
$$

Nonnegativity of $y$ and $u$ implies that $\Delta_{y} \geq 0$ and $\Delta_{u} \geq 0$, whence $k \geq 1$ and $1 \geq l$. But the last two inequalities contradict the precondition $l>k$. Thus, we have arrived at a conclusion. No diagonal $2 \times 2$-matrices $\mathrm{A}>\mathrm{O}$ and $A^{\prime}>O$ can satisfy the relations (10) except for $A^{\prime}=c A$. In other words, two commuting density operators $\rho \neq \rho^{\prime}$ with the same two-dimensional support cannot be cloned exactly. The statement has been checked for the case of three-dimensional support, where the details are more complicated. We omit them here. The conclusion seems to be valid for arbitrary (finite) dimensionality of the support, but we have not proved this yet.

As it is known, for commuting mixed states the broadcasting process may be applied [8, 9]. This is a deterministic operation $\mathcal{G}$ such that both the partial traces of operator $\mathcal{G}(\rho)$ on $\mathcal{H} \otimes \mathcal{H}$ are $\rho$, both the partial traces of operator $\mathcal{G}\left(\rho^{\prime}\right)$ are $\rho^{\prime}$. The conceivable broadcasting pairs are briefly discussed in Sect. 4.3 of [9]. The cloning is special strong form of broadcasting [8], when the relations (9) hold. Two commuting states can perfectly be cloned if and only if they are either orthogonal or identical [8]. This implies that two commuting density operators $\rho \neq \rho^{\prime}$ with the same support cannot be cloned. But probabilistic operations are beyond the scope of Ref. [8]. In this regard, our results contribute to the question about cloning of commuting mixed states. At least in two and three dimensions, commuting states $\rho \neq \rho^{\prime}$ with the same support cannot be cloned exactly, even if we extend action to all probabilistic operations.

Another application of the above results is related to no-cloning principle for orthogonal states in composite systems observed by Mor [10]. In the case of a composite system made of two subsystems, he emphasized the following. If the subsystems are only available one after the other then there are those cases that orthogonal states cannot be cloned [10]. But probabilistic operations are not seen into Ref. [10]. Let us revisit the example of two orthogonal states,

$$
\begin{equation*}
|\Phi\rangle=\cos \gamma|01\rangle+\sin \gamma|10\rangle, \quad|\Psi\rangle=\sin \gamma|01\rangle-\cos \gamma|10\rangle, \tag{15}
\end{equation*}
$$

given in [10]. The corresponding reduced density matrices of the first subsystem are

$$
\begin{equation*}
\rho_{\Phi}=\cos ^{2} \gamma|0\rangle\langle 0|+\sin ^{2} \gamma|1\rangle\langle 1|, \quad \rho_{\Psi}=\sin ^{2} \gamma|0\rangle\langle 0|+\cos ^{2} \gamma|1\rangle\langle 1| . \tag{16}
\end{equation*}
$$

Except for the cases $\sin \gamma=0$ or $\cos \gamma=0$, these operators have the same two-dimensional support. They are different for $\cos \gamma \neq \sin \gamma$. It follows from our reasons that mixed states (16) cannot be cloned exactly by probabilistic quantum operation. So, we can complete the main result of Ref. [10]. Under the described restriction on available subsystems, there are various cases when orthogonal states cannot be cloned exactly even via probabilistic operation. This kind of restriction is typical in quantum key distribution. Together with non-orthogonality of used states, the described restriction is also basic for security of quantum cryptography schemes [10]. So, we have reinforced the important result of Ref. [10] with respect to probabilistic cloning operations.
